

Core Performance Indicators of Switch Interfaces

AI Overview

Key performance indicators for switch interfaces include throughput, switching capacity, latency, packet loss, error rates, and port utilization, which collectively determine the efficiency and reliability of network switches.

Throughput measures the maximum data a switch can forward without dropping packets, typically expressed in packets per second (PPS) or bits per second (bps) such as Gbps or Tbps. It reflects the switch's ability to handle traffic, especially under high-load conditions with small packets, like VoIP or gaming traffic. Wire-speed forwarding indicates the switch can process packets at the maximum physical speed of its ports, regardless of packet size. Throughput is influenced by forwarding table size, port speed, and switch configuration.

Switching Capacity is the total amount of data the switch's internal architecture can handle simultaneously, calculated as the number of ports multiplied by the port rate and doubled for full-duplex operation. It is distinct from backplane bandwidth, which refers to the maximum data transfer capability of the switch's internal bus. High switching capacity ensures the switch can manage simultaneous traffic across all ports without congestion.

Latency measures the time it takes for a packet to traverse the switch from ingress to egress. Low-latency switches, often used in 5G or real-time applications, employ cut-through switching and optimized ASIC designs to minimize delay. Latency is critical for applications requiring ultra-reliable low-latency communication (URLLC).

Packet Loss and Error Rates Packet loss occurs when the switch cannot forward all incoming packets, often due to congestion or buffer limitations. Error rates include CRC errors, link errors, synchronization losses, and discarded frames due to buffer or timeout conditions
